Simultaneous phosphorus uptake and denitrification by EBPR-r biofilm under aerobic condition: effect of dissolved oxygen

Pan Yu Wong, Maneesha P. Ginige, Anna H. Kaksonen, Ralf Cord-Ruwisch, David C. Sutton and Ka Yu Cheng

ABSTRACT

A biofilm process, termed enhanced biological phosphorus removal and recovery (EBPR-r), was recently developed as a post-denitrification approach to facilitate phosphorus (P) recovery from wastewater. Although simultaneous P uptake and denitrification was achieved despite substantial intrusion of dissolved oxygen (DO > 6 mg/L), to what extent DO affects the process was unclear. Hence, in this study a series of batch experiments was conducted to assess the activity of the biofilm under various DO concentrations. The biofilm was first allowed to store acetate (as internal storage) under anaerobic condition, and then was subjected to various conditions for P uptake (DO: 0 – 8 mg/L; nitrate: 10 mg-N/L; phosphate: 8 mg-P/L). The results suggest that even at a saturating DO concentration (8 mg/L), the biofilm could up take P and denitrify efficiently (0.70 mmol e⁻/gTS·h). However, such aerobic denitrification activity was reduced when the biofilm structure was physically disturbed, suggesting that this phenomenon was a consequence of the presence of oxygen gradient across the biofilm. We conclude that when a biofilm system is used, EBPR-r can be effectively operated as a post-denitrification process, even when oxygen intrusion occurs.

INTRODUCTION

Low effluent concentrations for total phosphorus (TP) and total nitrogen (TN) are increasingly being imposed on wastewater treatment plants worldwide. Europe and North America in particular have enforced discharge limits of 0.1 mg/L for TP and 3 mg/L for TN (Boltz et al. 2015). While the strict TP limits are largely achieved through chemical precipitation, biological post-denitrification is applied to meet the TN discharge limit. With much of the readily biodegradable organic carbon in the influent being oxidised during upstream aerobic/anoxic oxidative processes, post-denitrification is heavily reliant on the addition of carbon sources (e.g. methanol) (Wei et al. 2014). The cost of adding external carbon is a significant burden to the wastewater industry, and one way to offset this cost is through resources recovery from wastewater.

Among many resources in wastewater, phosphorus (P) is of interest because it is a non-renewable resource, and its scarcity for agricultural purposes could potentially threaten global food security (Cordell et al. 2011). Wong et al. (2013) proposed and validated a post-denitrification process, termed enhanced biological phosphorus removal and recovery (EBPR-r), that facilitates nitrogen (N) removal but also enables P recovery from wastewater. The EBPR-r process involves two steps, in which a biofilm consisted of phosphate accumulating organisms (PAOs) is alternately exposed to a wastewater stream and a separate recovery stream. As the PAOs can use nitrate (NO₃⁻) as a final electron acceptor for P uptake, the first step of the process facilitates both denitrification and P removal from the wastewater. In the absence of soluble carbon in wastewater, the internal carbon storage polymers (i.e. such as poly-β-hydroxy-alkanoates; PHA) act as electron donors and an energy source to facilitate this step. The subsequent anaerobic step, the biologically captured P is released into a smaller recovery stream. External carbon (i.e. acetate) is added to facilitate P release, and the biofilm simultaneously replenishes its carbon reserves by intracellular storage of carbon supplied to the recovery
stream. The volume difference maintained between the wastewater and the recovery stream (e.g. ratio of 4:1) enables recovery of P as a concentrated solution.

It has been suggested that dissolved oxygen (DO) concentrations >0.2 mg/L inhibit denitrification (Gerardi 2003). In conventional post-denitrification processes, anoxic conditions prevail largely because of the rapid consumption of oxygen (O2) by heterotrophic bacteria during carbon oxidation. Facilitating an anoxic environment in a similar manner is not feasible in the EBPR-r process, as external carbon is supplied only to the recovery stream. Except for carbon stored intracellularly, no soluble carbon is available in the wastewater stream. Under these conditions, Wong et al. (2013) observed elevated DO concentrations (DO > 6 mg/L) during N and P removal, but surprisingly the high DO concentrations did not appear to inhibit denitrification and P removal.

Storage-driven denitrification is commonly observed in the simultaneous nitrification, denitrification and phosphorus removal processes (SNDPR) (Zeng et al. 2005; Lemaire et al. 2008). In which, nitrifiers make use of the O2 to facilitate partial nitrification under low DO concentration (<1 mg/L), and hence are largely responsible for creating the anoxic conditions for denitrification. Findings based on the SNDPR process are not directly useful for understanding denitrification in the EBPR-r process, which has been observed to take place at much higher levels of DO (>6 mg/L) with little contribution of nitrifiers (Wong et al. 2015). If large-scale EBPR-r is to be implemented, a clear understanding of the impact of DO on post-denitrification and P removal is critical.

Hence, the aim of this study was to explore the impact of DO on simultaneous storage-driven denitrification and P removal by an EBPR-r biofilm. The specific objectives included assessment of the importance of the biofilm structure, and the levels of DO that can be tolerated by the bacteria without impeding denitrification. First, batch experiments were conducted to quantify P uptake, NO3 removal and O2 consumption kinetics by an intact biofilm exposed to various concentrations of DO (0–8 mg/L) and NO3 (0–50 mg-N/L). Secondly, the EBPR-r biofilm was physically disturbed to investigate the effect of biofilm structure on the P and N removal efficiencies.

**MATERIALS AND METHODS**

**Reactor configuration and synthetic wastewater**

A laboratory scale sequencing batch biofilm reactor (master reactor) was operated continuously in EPBR-r configuration for a 2-year period, as described previously (Wong et al. 2013). A schematic diagram of the reactor process is shown in Figure S1 in the supporting document. In brief, 1,000 biofilm carriers (Kaldnes® K1 polyethene) were equally distributed among eight adjoining stainless steel mesh compartments. Over a 6-h cycle the biofilm carriers were alternately exposed for 4 h to a wastewater stream (7.2 L) for P uptake, and for 2 h to a separate recovery stream (1.8 L, 25% of the volume of the wastewater stream) for anaerobic P release.

Both the wastewater and recovery streams contained a standard growth medium consisting of (per L of DI water): 39 mg MgSO4, 20 mg CaCl2·2H2O, 11 mg NH4Cl (5 mg/L NH4·N), 200 mg NaHCO3 and 3 mL of a trace element solution (Wong et al. 2013). The wastewater stream also contained 8 mg-P/L phosphate (supplemented as 1 M phosphate buffer), 10 mg-N/L nitrate (as sodium nitrate) and 11.6 mg/L N-Allyli thiourea, the latter added to prevent nitrification during the P-uptake phase (Ginet et al. 1998). To restore intracellular PHA reserves during the anaerobic P release, 520 mg/L sodium acetate was added to the recovery stream, which corresponded to 400 mg/L chemical oxygen demand. Concentrated stock solutions (15×) of the media comprising each of the streams were prepared, and the pH was adjusted to 7.0 ± 0.2 using 2 M HCl. Defined volumes of the stock solution and deionised water were simultaneously pumped into the reactor at the beginning of each phase to achieve the desired concentrations.

**Kinetic experiments using intact biofilm**

To elucidate the use of O2 and NO3 by the EBPR-r biofilm when both electron acceptors were present, two sets of experiments were performed in duplication (Figure 1). (1) The activity of the biofilm was investigated using an initial
The concentrations of soluble NO$_3^-$ were normalised using the respective total biomass (TS) concentrations.

The percentage of electrons used for O$_2$ reduction was calculated by assuming that all the electrons from the storage were captured by either O$_2$ or NO$_3^-$.

Liquid samples were withdrawn and filtered for analysis of soluble NO$_3^-$, NO$_2^-$, and PO$_4^{3-}$-P. The size distribution of the suspended biomass was measured using a laser particle sizer (Malvern Master Sizer), was determined by an external laboratory (CSIRO, Division of Mineral Particle Analysis Service, Waterford, Australia).

**Kinetic experiments using dislodged biomass**

To confirm if the observed denitrification in the presence of O$_2$ was due to the presence of an oxygen gradient across the biofilm, kinetic experiments were conducted using biomass dislodged from the carriers. To obtain the biomass, biofilm carriers (~330) were removed from the master reactor at the end of the P-uptake phase (low in PHA storage) and placed into growth medium in a 500 mL flask. Attached biofilm was physically removed by shaking the carriers in standard medium for 2 min. To break down the size of the flocs, the suspended biofilm was repeatedly drawn up and expelled through a needle (gauge 19–1/2) using a 50 mL syringe. An acetate-containing recovery stream (200 mL) was added to the dislodged biomass for PHA replenishment for 2 h. Thereafter, the biomass was concentrated by centrifugation and washed twice with standard medium (without N, P and C) under anaerobic condition to remove any excess acetate. The PHA-rich biomass was then resuspended in 220 mL standard medium under anaerobic conditions for use in batch experiments.

Four batch reactors (250 mL Schott bottles) were operated in parallel to compare the denitrification ability of the biomass in the presence of 10 mg-N/L NO$_3^-$ for 4 h: (1) oxygenated, with 8 mg-P/L phosphate; (2) oxygenated, without phosphate; (3) anoxic, with 8 mg-P/L phosphate; and (4) anoxic, without phosphate. To initiate the experiment, 50 mL of suspended biomass was added to 200 mL of synthetic wastewater. The oxygenated and anoxic condition was achieved by continuously sparging air and nitrogen into the liquid, respectively. Mixing was achieved using a multi-position magnetic stirrer (400 rpm; RT10, IKA). To confirm the observation of denitrification under oxygenated conditions, on a different day the batch tests for the aforementioned conditions (1) and (2) were repeated.

Liquid samples were withdrawn and filtered for analysis of soluble NO$_3^-$, NO$_2^-$, and PO$_4^{3-}$-P. The mixed liquor suspended solids (MLSS) value for the suspended biomass was measured according to the standard method (American Public Health Association American Water Works Association & Water Environment Federation (U.S.) 1995). The MLSS concentration and the NO$_3^-$ removal rate were normalised with the solids concentration, and expressed as mmol/gMLSS/h. The size distribution of the suspended biomass flocs, measured using a laser particle sizer (Malvern Master Sizer), was determined by an external laboratory (CSIRO, Division of Mineral Particle Analysis Service, Waterford, Australia).
RESULTS AND DISCUSSION

Storage-driven denitrification and P uptake at very high DO concentrations

In a previous study we observed that an EBPR-r biofilm could up take phosphate and remove NO$_3$ in the presence of saturating DO (Wong et al. 2015). However, as both NO$_3$ and O$_2$ were provided to the biofilm, we were unable to distinguish the independent effects of these electron acceptors. Hence, in the present study batch experiments were conducted to assess the influence of each of O$_2$ and NO$_3$ as sole electron acceptors on P removal. The EBPR-r biofilm could readily use either O$_2$ or NO$_3$ for P uptake, or both (Figure S2 of supporting information). The highest PUR was observed when O$_2$ was provided, either alone (0.038 mmol-P/gTS•h) or in combination with NO$_3$ (0.043 mmol-P/gTS•h). When NO$_3$ was used as the sole electron acceptor, the PUR was markedly reduced by 30%, from 0.043 to 0.030 mmol-P/gTS•h (Table 1). According to Kuba et al. (1996), the energy (adenosine triphosphate) production during oxidative phosphorylation with NO$_3$ as the electron acceptor is approximately 40% less than occurs with O$_2$ as the acceptor. While the reduced energy from oxidative phosphorylation based on NO$_3$ could have contributed to the 30% reduction in PUR, the possible role of a low-abundance denitrifying PAO population in the biofilm should not be overlooked.

As expected, the highest NO$_x$ removal rate (0.076 mmol-N/gTS•h) was observed when NO$_3$ was supplied as sole electron acceptor. When supplemented with DO (8 mg/L), 70% of the denitrification efficiency of the biofilm was retained (Table 1), indicating that the enriched EBPR-r biofilm could denitrify under a very high DO concentrations.

The oxygen gradient across the biofilm enabled denitrification in the presence of DO

To elucidate the effect of DO and NO$_3$ loading on the P uptake and denitrification behaviour of the EBPR-r biofilm, two sets of experiments were conducted in which the concentration of one electron acceptor was maintained constant while the concentration of the other was varied. The concentration profiles for each experiment set are illustrated in the supplementary data Figure S3.

At a NO$_3$ concentration of 10 mg-N/L, increasing the bulk DO concentration from 0 to 8 mg/L increased the PUR by 43% (from 0.030 to 0.043 mmol/gTS•h) (Figure 2(a)). A linear relationship ($R^2 = 0.999$) was obtained between the OUR and the applied bulk DO concentration (Figure 2(b)).

Figure 2 | Effect of bulk DO (0–8 mg/L) and initial NO$_3$ (0–50 mg-N/L) concentration on: (a) and (e) phosphate uptake rate; (b) and (f) OUR and NO$_3$-N removal rate; (c) and (g) electron accepting rate for O$_2$ and NO$_3$; and (d) and (h) the percentage of electrons used for PHA oxidation using electrons generated by O$_2$ and NO$_3$ reduction.
Such a first order kinetic behavior suggested that the biofilm was limited by $O_2$ (Meyer et al. 2005). Increasing the bulk water DO concentration from 0 to 8 mg/L could result in deeper penetration of $O_2$ into the biofilm, triggering the higher OURs (from 0 to 0.091 mmol/gTS*h) and the lower denitrification rates (1.5-fold reduction from 0.076 to 0.052 mmol-N/gTS*h) (Figure 2(b)). This result confirms the presence of an oxygen gradient in the biofilm, with the inner anoxic environment facilitating the observed denitrification despite the bulk water being saturated with oxygen.

In contrast, when the bulk DO concentration was fixed at 8 mg/L, increasing the NO\textsubscript{3} concentration from 0 to 50 mg-N/L resulted in an increase in the denitrification rate (from 0 to 0.096 mmol-N/gTS*h) (Figure 2(f)). This result was expected because increased NO\textsubscript{3} availability in the bulk water could facilitate the penetration of NO\textsubscript{3} into the deeper anoxic layers of the biofilm, as observed in conventional EBPR process under anoxic conditions (Ahn et al. 2001; Yuan & Oleszkiewicz 2010; Zhou et al. 2010). In terms of P uptake, only a slight decrease in the PUR was observed with increasing NO\textsubscript{3} concentration (16% of overall inhibition, from 0.038 to 0.032 mmol/gTS*h) (Figure 2(e)). No increase in PUR and a continuous increase in denitrification (evident in Figure 2(f)) could be a result of some NO\textsubscript{3} being utilised by denitrifying glycogen accumulating organisms (denitrifying GAOs) in the biofilm. The slight decrease in PUR is consistent with the findings of Yuan & Oleszkiewicz (2010), who observed an increased anoxic PUR and a decreased aerobic PUR with increasing NO\textsubscript{3} concentrations in the bulk water. It is also possible that when the NO\textsubscript{3} concentration increased in the bulk water, some PAOs were able to switch from using $O_2$ as electron acceptor to use of NO\textsubscript{3}. With more PAOs using NO\textsubscript{3} as electron acceptor, the OUR and PUR may have decreased. Whether the elevated level of $O_2$ inhibited the activity of denitrifying PAOs remains unclear, and should be the subject of further research.

**More than half of the stored reducing power was used for denitrification at 8 mg/L of DO**

In the absence of a soluble carbon, the observed P uptake and denitrification activities were driven by internal carbon storage (e.g. PHAs) in the EBPR-r biofilm. To compare the reduction kinetics of NO\textsubscript{3} and $O_2$ for the biofilm, the OUR and NO\textsubscript{x} removal rates (Figure 2(b) and 2(f)) were transformed into a common unit (electron accepting rate) (Figure 2(c) and 2(g)), and were also expressed as a percentage of the electrons used for internal carbon oxidation (Figure 2(d) and 2(h)).

At a bulk DO concentration of 8 mg/L and a NO\textsubscript{3} concentration of 0 mg-N/L, the electrons stored in the biofilm were predominately used to reduce $O_2$ at a maximum electron accepting rate of 0.46 mmol e\textsuperscript{-}/gTS*h (Figure 2(g)). With increasing bulk water NO\textsubscript{3} concentration the electron reduction rate for $O_2$ decreased only slightly, whereas the electron reduction rate for NO\textsubscript{3} increased dramatically. At NO\textsubscript{3} concentration of approximately 8 mg-N/L, the biofilm appeared to be transferring electrons at a similar rate to both $O_2$ and NO\textsubscript{3}. At a bulk water NO\textsubscript{3} concentration exceeding 8 mg-N/L, NO\textsubscript{3} became the dominant electron acceptor (>50%) (Figure 2(h)). Thus, a NO\textsubscript{3} concentration of >8 mg-N/L in the wastewater is favourable for efficient NO\textsubscript{3} reduction.

At a NO\textsubscript{3} concentration of 10 mg-N/L and a DO concentration of 0 mg/L, the electrons stored in the biofilm were solely used to reduce NO\textsubscript{3} at a maximum electron accepting rate of 0.98 mmol e\textsuperscript{-}/gTS*h (Figure 2(c)). When the DO concentration increased from 0 to 8 mg/L, the proportion of electrons accepted by $O_2$ gradually increased from 0 to 35% (Figure 2(d)). It is noteworthy that even at such a high bulk water DO concentration the biofilm was able to channel approximately 65% of the electrons to NO\textsubscript{3} reduction. This unique ability of the biofilm to reduce NO\textsubscript{3} in the presence of DO is critical for the EBPR-r process, and is probably a consequence of the presence of an oxygen gradient across the biofilm, as discussed above.

**The biofilm structure is essential for denitrification in the presence of $O_2$**

To determine whether the cells in the biofilm could continue to denitrify when the DO gradient was disrupted, the biofilm was removed from the carriers and physically disturbed to form suspended aggregates (mean size 185 ± 11 μm). The aerobic and anoxic ratio difference of P uptake (PUR\textsubscript{aer}/PUR\textsubscript{ana}) and denitrification activities of the suspended biomass (MLSS of 1.03 ± 0.05 g/L) were compared with that of the intact biofilm.

Similar to the intact biofilm, the suspended biomass showed the highest PUR (0.53 mmol-P/gMLSS*h) when both $O_2$ and NO\textsubscript{3} were provided as electron acceptors (Table 2). When NO\textsubscript{3} was the sole electron acceptor the PUR decreased by 38%, which is consistent with the observed decline in the previous experiments with the intact biofilm (~50% in Table 1). Thus, the decreased PUR observed with NO\textsubscript{3} was not caused by the biofilm structure, but rather appeared to be influenced by the type of electron acceptor.
As with the intact biofilm, the highest level of denitrification by the suspended culture was observed in the absence of DO (Table 2). However, when O₂ (DO > 6 mg/L) was introduced into the bulk water a 6-fold decrease in the denitrification rate (from 1.00 to 0.16 mmol-N/gMLSS*h) was observed. This was remarkably different from the intact biofilm, for which the respective decline in the denitrification rate was only 1.5-fold (Table 1). One plausible explanation for the decrease in denitrification activity after the disruption of oxygen gradient is the inhibition of nitrate reductase, which is a membrane-bound enzyme that catalyses the reduction of NO₃⁻ to NO₂⁻, and is sensitive to O₂ (Ogunseitan 2005). Under anoxic conditions, the rate of reduction of NO₃⁻ (2.23 mmol-N/gMLSS*h) far exceeded that of NO₂⁻, resulting in the accumulation of the NO₂⁻ observed in this study (an accumulation rate of 2.39 mmol-N/gMLSS*h, Figure 3(c)). Only when NO₃ became limiting was an overall reduction in NOₓ observed. Accumulation of NO₂⁻ is a common observation during denitrification and has been extensively discussed in the literature (Ahn et al. 2001; Zhou et al. 2010). Under aerobic conditions the nitrate reductase enzyme was exposed to O₂, resulting in inhibition of the enzyme and a significant decrease in the NO₃⁻ reduction rate (Figure 3(a)). These results demonstrate that maintenance of the biofilm structure for bacterial growth is critical for the EBPR-r process to achieve satisfactory rates of denitrification, particularly when strict anoxic conditions cannot be maintained.

The dependency of denitrification on P

The observed denitrification in suspended biomass could be performed by either PAOs or other non-PAO bacteria, including GAO. By definition, GAOs do not require storage of P under either aerobic or anoxic conditions (Oehmen et al. 2006). To investigate the denitrification activities of non-PAO organisms, the suspended biomass experiment was conducted aerobically and anoxically with no P in the bulk water.

Under anoxic conditions the absence of phosphate decreased the NOₓ removal rate only by 22%, from 1.00 mmol-N/gMLSS*h in the presence of P to 0.78 mmol-N/gMLSS*h in the absence of P (Table 2). This confirmed

P. Y. Wong et al. | Phosphorus uptake and denitrification under aerobic condition | Water Science & Technology | in press | 2015

Uncorrected Proof
the role of non-PAO organisms (e.g. denitrifying GAOs) in biofilms carrying out denitrification. However, exposing the suspended biomass to aerobic conditions in the absence of phosphate resulted in a complete inhibition of denitrification (Figure 3(b)), indicating that the non-PAO denitrifiers in the EBPR-r culture were unable to denitrify when exposed to O₂. It is plausible that they had reduced affinity for NO₃ than did the PAOs, or that they were more sensitive to O₂. Alternatively, it is possible that the denitrifying GAOs predominately occupied the inner parts of the biofilm, where the penetration of O₂ was reduced (Lemaire et al. 2008), as has been reported for the granules enriched in the SNDRP process.

Implications of the study

EBPR-r is a novel post-denitrification process that enables P recovery. The success of this strategy depends on whether denitrification can be efficiently driven by the reducing power stored in the biofilm. The lack of soluble carbon and ammonia in the influent of this process could result in an elevated bulk water DO, which might affect the denitrification process. Our previous study suggested that the EBPR-r process can facilitate denitrification without the need to maintain a strictly anoxic environment in the bulk water (Wong et al. 2013). This was confirmed in the current study, where 60% of the reducing power stored in the biofilm was found to be expended on denitrification, even when the bulk water DO concentration was near saturation (8 mg/L). However, the denitrifying ability of the EBPR-r process was remarkably compromised when the biofilm structure was physically disturbed, implying that maintenance of the biofilm structure is critical for the success of EBPR-r as a post-denitrification strategy when oxygen intrusion occurs.

CONCLUSION

The results of this study suggest that:

- the EBPR-r biofilm facilitated P and N removal in a process that was not sensitive to oxygen intrusion;
- at a NO₃ concentration of 10 mg-N/L, increasing the DO concentration (from 0 to 8 mg/L) increased the PUR by 43% and decreased the denitrification rate by 31%;
- at a DO concentration of 8 mg/L, increasing the NO₃ concentration (from 0 to 50 mg-N/L) increased the denitrification rate (from 0 to 0.096 mmol-N/gTS*h).

In summary, this study highlights the importance of the EBPR-r biofilm structure in enabling denitrification to take place at the same time as P removal for recovery. The data also suggest some operational boundaries (e.g. specific DO and NO₃ concentrations in the influent) necessary for the EBPR-r biofilm to reduce P and N to acceptable levels in the effluent.
