Background: Accurate identification of eosinophils in the gastrointestinal (GI) tract of dogs with eosinophilic GI disease (EGID) by histological evaluation is challenging. The currently used hematoxylin and eosin (H&E) staining method detects intact eosinophils but does not detect degranulated eosinophils, thus potentially underrepresenting the number of infiltrating eosinophils.

Objective: To develop a more sensitive method for identifying and quantifying both intact and degranulated eosinophils to diagnose EGID more accurately.

Methods: Endoscopically obtained paraffin-embedded intestinal biopsy specimens from dogs with GI signs were examined. The study groups were dogs with eosinophilic enteritis (EE), lymphoplasmacytic and mixed enteritis, and control dogs with GI signs but no histologic changes on tissue sections. Consecutive sections were immunolabeled with monoclonal antibodies (mAbs) against the eosinophil granule protein eosinophil peroxidase (Epx) and stained by H&E, respectively. The number of eosinophils was manually quantified and classified as intact or degranulated.

Results: The number of intact eosinophils detected in Epx mAb-labeled duodenal sections was significantly higher compared with that in H&E-stained sections, with a similar relationship noted in the colon and stomach. The Epx mAb allowed the unique assessment of eosinophil degranulation. The number of intact and degranulated eosinophils was significantly higher in duodenal lamina propria of the EE and mixed group compared to the control group.

Conclusion: Immunohistochemical detection of Epx provides a more precise method to detect GI tract eosinophils compared to H&E staining and could be used as an alternative and reliable diagnostic tool for assessment of biopsy tissues from dogs with EGID.

dog, eosinophil peroxidase, diagnostic marker, gastrointestinal inflammation

INTRODUCTION

Eosinophilic gastrointestinal disease (EGID) includes a spectrum of disorders defined by eosinophilic inflammation in ≥1 sites (ie, esophagus, stomach, intestine, and colon) of the GI mucosa without any known cause for such infiltration (eg, drug reactions, parasitic infections, malignancy, and other causes).1,2 Eosinophils play a crucial role in innate and adaptive immunity of the GI tract by participating in host defense against luminal pathogens and maintaining intestinal epithelial homeostasis.3-5 In dogs, IBD is the term used to describe persistent or recurrent GI signs (eg, weight loss, vomiting, and diarrhea) and histopathological evidence of intestinal inflammation without underlying...
causes (e.g., infection, endocrine, and neoplastic disease). Muco-
sal inflammation is a characteristic histopathological feature of IBD and
the primary forms of small intestinal IBD in dogs are LPE, character-
ized by increased numbers of lymphocytes and plasma cells, and EE,
which is characterized by infiltration predominantly of eosinophils.

Eosinophils are multifunctional granulocytes that, upon activation,
play a critical role in regulating innate and adaptive immune responses
by release of various mediators such as cytokines, growth factors,
chemokines, and cytotoxic granule proteins (degranulation). Pre-
formed cytotoxic granule proteins such as eosinophil cationic protein,
Epx, and major basic protein released by activated eosinophils during
inflammation can contribute to tissue damage and dysfunction.9–12
Therefore, it is important to accurately detect not only intact eosino-
phils with intracellular granule proteins but also extracellular release
of granule proteins by activated eosinophils, to obtain a better under-
standing of the contribution of eosinophil activation to disease patho-
genesis. The pathophysiological effects associated with eosinophilic
infiltration of the GI tract remain poorly defined.6 Histological eval-
uation of endoscopic biopsy specimens is performed frequently in the
diagnosis and management of dogs with IBD. This evaluation entails
detailed characterization of the inflammatory infiltrate (ie, lympho-
cytes, plasma cells, and eosinophils), the area affected (ie, focal or gen-
eralized, superficial, or deep), the severity of inflammation (ie, mild,
moderate, and severe), and any microarchitectural changes (ie, villus
fusion or atrophy and fibrosis).13

The assessment of GI mucosal inflammation, including the quanti-
fication of eosinophils, by H&E staining of biopsy tissues in conjunc-
tion with exclusion of underlying disease is used as a guideline in the
diagnosis of IBD.14 However, H&E staining can only detect intact but
not degranulated, eosinophils, and therefore may underrepresent the
extent of eosinophilic infiltration.15 Although eosinophils are present
in the normal small intestinal mucosa, the distinction between the
upper limit of normal and abnormally increased tissue eosinophils is
not clearly defined using H&E staining.14,16,17 Using jejunal tissue col-
lected at necropsy examination from dogs with IBD, we previously
have demonstrated that IHC using a mAb specific for the eosinophil
granule protein Epx allows reliable morphological identification of
degranulated as well as intact eosinophils and could serve as a tool for
quantitative evaluation of eosinophils in the small intestine.15 Our
specific aim in the present study was to quantify and compare eosino-
ophil counts by H&E versus Epx mAb IHC of endoscopically obtained
biopsy specimens from a larger, clinically well-defined cohort of dogs
to further our understanding of the role of eosinophils and eosinophil
degranulation in intestinal inflammation in dogs.

2 | MATERIALS AND METHODS

2.1 | Animals and samples

Thirty dogs (17 male and 13 female) were included in our retrospec-
tive study based on duodenal histopathology of endoscopic biopsy
specimens from cases submitted to the Pathology Unit of University
of Bristol, Bristol, United Kingdom. Dogs were of 17 different breeds:
Terrier-cross (n = 2), German Shepherd (n = 3), Labrador Retriever
(n = 6), Dachshund (n = 2), Jack Russell Terrier (n = 3), Cross-breed
(n = 2), Cavalier King Charles Spaniel (n = 2), and 1 each of the follow-
ing breeds: Miniature Schnauzer, Pit Bull Terrier, Saluki, Doberman
Pincher, Boxer, Staffordshire Bull Terrier, Lurcher, Chihuahua,
Rhodesian Ridgeback, and Foxhound. The study population included
dogs with EE (n = 10; median age, 5.5 years, with a mean ± standard
development [STD] of 5.5 ± 3.8 years) and dogs with mixed eosinophilic/LPE
(n = 10; median age, 3.5 years, with a mean ± STD of 4.5 ± 3.1 years).
Because endoscopic biopsy of healthy dogs is not permitted at the Pathology Unit of University of Bristol, the control
group (n = 10; median age, 3.5 years, with a mean ± STD of 4.5 ± 2.8 years) comprised dogs with a variety of GI signs (eg, regurgi-
tation, vomiting, weight loss, intermittent diarrhea, and abdominal
pain) requiring endoscopic investigation, but in which intestinal biopsy
specimens were assessed as histologically normal. All dogs underwent
standard investigations consisting of hematological examination,
sodium biochemistry, serum folate and cobalamin concentrations, basal
cortisol concentration or ACTH stimulation test, urinalysis, and
abdominal imaging (transabdominal ultrasound examination, radi-
ographs, or computed tomography). Fecal parasitological examinations
were performed in all dogs unless they had recently undergone trial
treatment with fenbendazole before referral, and all were negative.
Records before referral were sometimes incomplete, but no dog was
reported to have responded to a diet trial, and all dogs had been on a
regular diet without administration of any immunosuppressive agents
or antibiotics for at least 2 weeks before endoscopy. Final diagnoses
included pancreatitis, megasaphogus protein-losing nephropathy,
food-responsive enteropathy, hiatal hernia, or unknown.

Available tissue consisted of adequate endoscopically obtained
biopsy specimens of the stomach (fundus, n = 30; antrum, n = 24),
duodenum (n = 30), and colon (n = 10) that were formalin fixed and
paraffin embedded. The original histopathology report for each dog
provided information on 4 morphologic variables (ie, epithelial injury,
cypt distension, lacteal dilatation, and mucosal fibrosis) and 4
inflammatory variables (intraepithelial lymphocytes, LP lymphocytes
and plasma cells, LP eosinophils, and LP neutrophils) in accordance with
the World Small Animal Veterinary Association guidelines.13 Each
variable was scored by a veterinary pathologist (MJD) as: 0 = normal,
1 = mild, 2 = moderate, or 3 = marked, as previously described.13
Because architectural changes were limited, histopathological severity
was quantified by the numerical score attributed to the inflammatory
infiltration. In addition, the dominant inflammatory population was
recorded and biopsy specimens were classified as containing only
eosinophilic or lymphoplasmacytic and eosinophilic (referred to as
mixed enteritis) inflammation. Based on this scoring system, 8 dogs
were scored as having mild EE or mixed enteritis and 12 dogs were
scored as having moderate EE or mixed enteritis.

2.2 | Histology and immunohistochemistry

Serial 4-μm-thick sections were cut from each paraffin block. Section
1 was stained with H&E, whereas Sections 2 and 3 were
immunolabeled with Epx mAb (Mayo Clinic, Scottsdale, Arizona) and
normal mouse IgG (negative control, Sigma-Aldrich, St. Louis,
Missouri), respectively, as previously described.15 Slides were
evaluated using an Olympus BX53 upright light microscope and photomicrographs were acquired using an Olympus DP73 camera and Olympus cellSens Software (Olympus, Center Valley, Pennsylvania).

2.3 Quantification of eosinophils

Eosinophils were quantified in each H&E-stained and Epx mAb-labeled tissue section in a blinded fashion (IB). Several randomly selected sections were evaluated separately by an American College of Veterinary Pathologists Diplomate (DS) to ensure consistency in quantitation. For each case, the 5 largest biopsy tissue sections on the slide were evaluated for each organ. For each tissue section, eosinophils were manually quantified in contiguous ×400 fields spanning the entire section (range, 10-25 fields, depending on the size of the section). Eosinophils were classified as either intact or degranulated. Degranulated eosinophils were identified based on immunopositive Epx staining in the extracellular space (ie, free cytoplasmic granules, extracellular matrix deposition of eosinophil secondary granule proteins, or both), which corresponded to an adjacent nucleus that fitted the morphologic criteria for an eosinophil (ie, hyperchromatic bilobed nucleus) as described previously. In the case of duodenum, the microscopic location of each cell was defined as either upper (villus) or lower LP (between the muscularis mucosa and crypts) and for the stomach the location was defined as either antrum or fundus. Degranulated eosinophils were quantitated only in duodenal biopsy specimens (not stomach and colon). The average number of eosinophils per field first was calculated for each region (ie, stomach [antrum and fundus], duodenum [upper and lower LP], and colon) and type (H&E [intact], Epx [intact], and Epx [degranulated]) combination for each dog and used for all further analyses.

2.4 Statistical analysis

Samples from dogs diagnosed as having marked inflammation based on histopathological scoring were combined with those with moderate cellular infiltration as a single group in the statistical analysis. Visual inspection indicated that the data were not normally distributed, with substantial skew and several outlying points. To compare the 2 measurement types for intact eosinophils, H&E (intact) and Epx (intact), paired Wilcoxon tests were performed for each region separately. To compare the disease groups (control, EE, and mixed) and severity levels (control, mild, and moderate) for each duodenum region (upper LP and lower LP) and type (Epx only) combination, pairwise Wilcoxon tests were performed, with P values corrected for multiple comparisons within each region and type using the Bonferroni-Holm correction. Statistical analysis was performed using R Statistical Software (version 3.4.3). All tests were considered significant at a value of P ≤ .05.

3 RESULTS

3.1 Evaluation of eosinophil infiltration by H&E staining versus Epx mAb immunolabeling

H&E-stained sections of the duodenum from dogs with intestinal inflammation (EE or mixed enteritis) disclosed the presence of a mixed cellular infiltrate consisting primarily of eosinophils or a mixture of eosinophils, lymphocytes, and plasma cells. Duodenal sections of control dogs did not show any abnormal cellular infiltrates. The density of eosinophil infiltration in duodenal sections of these groups of dogs after H&E staining was quantified by manual counting and then compared with eosinophil numbers quantified after IHC with Epx mAb. The number of eosinophils detected per ×400 microscopic field after Epx mAb IHC in both the upper and lower LP was significantly higher than that detected in H&E-stained sections in each of the groups in both regions (Figure 1). This finding was consistent in other regions of the GI tract (ie, colon and stomach [fundus and antrum]). Quantitative assessment of intact eosinophils detected by H&E staining and Epx mAb IHC for each region of the GI tract for individual dogs is shown in Figure 2. In all cases, the number of intact eosinophils detected after Epx mAb IHC was higher than that detected by H&E staining, thus demonstrating that routine H&E staining alone underrepresents the number of eosinophils present.

Although H&E staining detected only intact eosinophils in duodenal sections from dogs with eosinophilic or mixed inflammation, Epx IHC easily allowed identification of intact eosinophils based on the prominent dark red-brown color within intracellular membrane-bound secondary granules and as well as degranulated eosinophils with diffuse extracellular granule staining (Figure 3). This finding is consistent with our previous study using jejunal tissue collected at the time of necropsy examination from dogs with IBD in which Epx IHC detected both intact and degranulated eosinophils. Representative H&E-stained and Epx-labeled images showing the presence and distribution of eosinophils in the lower and upper LP of the duodenum of control dogs and dogs with EE or mixed enteritis are shown in Figure 4.

3.2 Quantitative assessment of intact and degranulated eosinophils after Epx mAb labeling

Next, the number of intact and degranulated eosinophils in the upper and lower regions of the duodenal LP in dogs with EE and mixed
enteritis and control dogs was quantified based on Epx IHC. A significantly higher number of intact and degranulated eosinophils was detected in the upper and lower LP of the samples from dogs with EE and mixed enteritis compared with the number of intact and degranulated eosinophils in these regions in control dogs. The number of intact and degranulated eosinophils in the upper and lower regions of the LP of dogs with EE and mixed enteritis was not significantly different from each other (Figure 5).

In terms of disease severity (EE and mixed enteritis combined), the number of intact eosinophils detected by Epx IHC was significantly higher in the upper and lower LP in dogs with mild and moderate disease compared with control dogs (Figure 6). Furthermore, the number of intact eosinophils in the upper and lower LP of dogs with moderate disease was significantly higher than in dogs with mild disease. In the case of degranulated eosinophils, compared with control dogs, the number of these cells was significantly higher in the upper and lower LP in dogs with moderate disease and only in the upper LP for dogs with mild disease. No significant difference in the number of degranulated eosinophils was noted between dogs with mild and moderate disease in the upper or lower LP.

4 | DISCUSSION

Eosinophils are present in the healthy human and canine intestine in variable number. Abnormal accumulation of eosinophils in the intestine in the absence of other underlying causes (eg, parasitic infections) is a characteristic feature of EGID, including IBD. Staining of duodenal biopsy specimens with H&E for histopathological evaluation is routinely performed during diagnosis of IBD in dogs. In a previous study, we determined that unlike H&E staining, which detects only intact eosinophils, Epx IHC allows reliable identification of intact and degranulated eosinophils in jejunal tissue (collected at necropsy) of dogs with IBD, and potentially could allow quantitative analysis of eosinophils in the small intestine. In the current study, we have extended these findings to endoscopically obtained biopsy specimens from the stomach, duodenum, and colon of dogs with GI inflammation (EE or mixed enteritis) and confirmed the utility of this technique in eosinophil identification and quantitation using clinically relevant samples.

Evaluation of serial sections of duodenal biopsy specimens from control dogs and dogs with either EE or mixed enteritis that were stained with H&E and labeled with Epx mAb indicated that Epx mAb-based IHC consistently results in detection of significantly higher numbers of intact eosinophils relative to H&E staining. A similar finding was observed on evaluation of serially stained sections (using H&E and Epx mAb) from the stomach (antrum and fundus) and colon of these dogs. These findings suggest that quantification of eosinophil infiltration based on H&E staining is likely to be an underrepresentation of the

**FIGURE 2** Quantitative assessment of intact eosinophils detected by hematoxylin and eosin (H&E) staining and eosinophil peroxidase (Epx) immunolabeling for different regions of the gastrointestinal tract. Average number of positively stained/labeled intact eosinophils per high-power field at ×400 magnification in serial sections of colon, duodenum (upper LP and lower LP), and stomach (antrum and fundus) stained with H&E and Epx monoclonal antibody immunohistochemistry, respectively. Data for individual dogs in the control, eosinophilic (mild and moderate), and mixed (mild and moderate) enteritis groups are shown.

**FIGURE 3** Eosinophil degranulation assessed by eosinophil peroxidase (Epx) immunohistochemistry (IHC). The presence of intact eosinophils is noted in hematoxylin and eosin (H&E)-stained (left) and Epx-labeled (right) sections. Blue arrows in H&E-stained section indicate intact eosinophils. The fine detail of eosinophil granules within the cytoplasm of intact eosinophils (black arrows) and in the extracellular matrix (red arrows) indicating degranulation is noted only after Epx IHC. Scale bar = 20 μm
Difficult-to-diagnose eosinophilic esophagitis and gastroesophageal reflux disease. In another study using lung biopsy specimens from patients with acute lung injury, a 10-fold higher sensitivity in the detection of eosinophils was achieved by IHC with Epx mAb relative to H&E-stained sections, resulting in the identification of higher numbers of eosinophils in these patients compared with controls in whom differences using H&E staining alone were not significant. Similar findings were observed in canine skin in which Epx mAb IHC detected significantly higher numbers of eosinophils as compared to H&E staining. Based on our findings of enhanced detection of intact eosinophils by Epx mAb-based IHC relative to H&E staining, this method could be used to accurately assess eosinophilic inflammation in formalin-fixed and paraffin-embedded tissues from the duodenum, stomach and colon to improve diagnostic sensitivity for EGID in dogs.

Eosinophilic gastrointestinal disease often is caused by food allergen-driven Th2 inflammation that is likely to be responsible for the predominant infiltration of eosinophils. When activated,

![FIGURE 4](image-url) Eosinophils in duodenum of control, eosinophilic enteritis, and mixed enteritis groups of dogs by hematoxylin and eosin (H&E) staining and eosinophil peroxidase (Epx) labeling. Distribution of eosinophils within the upper and lower lamina propria (LP) of control, eosinophilic, and mixed enteritis groups of dogs. H&E-stained sections are on the left, and Epx IHC sections on the right. Note the ease in observing eosinophils in Epx-labeled versus H&E-stained sections in the upper and lower LP within each group. Scale bar = 20 μm.

![FIGURE 5](image-url) Quantitation of intact and degranulated eosinophils in duodenal biopsy specimens based on disease type. Average number of positively labeled intact and degranulated cells per high-power field at ×400 magnification in the upper and lower lamina propria of control (Con) dogs and dogs with eosinophilic enteritis (Eos) or mixed enteritis (Mix) after eosinophil peroxidase monoclonal antibody immunohistochemical staining and eosinophil peroxidase (Epx) labeling. Distribution of eosinophils within the upper and lower lamina propria (LP) of control, eosinophilic, and mixed enteritis groups of dogs. H&E-stained sections, resulting in the identification of higher numbers of eosinophils as compared to H&E staining.21 Based on our findings of enhanced detection of intact eosinophils by Epx mAb-based IHC relative to H&E staining, this method could be used to accurately assess eosinophilic inflammation in formalin-fixed and paraffin-embedded tissues from the duodenum, stomach and colon to improve diagnostic sensitivity for EGID in dogs.

![FIGURE 6](image-url) Quantitation of intact and degranulated eosinophils in duodenal biopsy specimens based on disease severity. Average number of eosinophil peroxidase-positive intact and degranulated cells per high-power field at ×400 magnification in the upper and lower lamina propria of control (Con) dogs and dogs with mild or moderate (Mod) disease (eosinophilic and mixed enteritis groups combined in this analysis) is shown. Histopathological severity is based on the cumulative numerical score determined according to World Small Animal Veterinary Association guidelines.
Eosinophils can secrete various preformed inflammatory cytokines such as interleukin (IL)-4, IL-5, IL-10, IL-12, and IL-13 as well as growth factors (eg, transforming growth factor [TGF]-β), chemokines (regulated on activation, normal T cell expressed and secreted and eotaxin-1), lipid mediators (platelet-activating factor and leukotriene C4), and cytotoxic granule proteins.20 These inflammatory mediators are known to induce various effects such as up-regulation of adhesion molecules to modulate cellular trafficking and recruitment, mucus secretion, tissue remodeling, and impairment of barrier integrity,24,25 which can contribute to disease progression. For example, eosinophil-derived TGF-β is linked to tissue remodeling and induction of the extracellular matrix protein periostin in patient biopsy specimens which increases eosinophil infiltration in the mucosal layer, thus facilitating disease pathogenesis.26,27 Furthermore, as indicated above, granule proteins such as eosinophil cationic protein, Epx, and major basic protein released by activated eosinophils during inflammation can contribute to tissue damage (alter barrier function) and dysfunction (diarrhea with bleeding).9–12 Deficiency of eotaxin-1, the eosinophil-specific chemokine, or blockade of its receptor (CCR3) resulting in depletion of eosinophils has been shown to attenuate inflammation in experimental models of IBD.9,28 thus supporting the overall importance of eosinophil involvement in EGID.

One of the limitations of H&E staining is its inability or poor ability to detect degranulated eosinophils.15 Studies in patients with different forms of GI eosinophilic inflammation have shown increased numbers of activated eosinophils and increased concentrations of extracellular granule protein, suggesting that these cells may be important players in promoting and mediating inflammation in the intestinal mucosa.29–32 Therefore, it is important to be able to reliably detect and quantify both intact and degranulated eosinophils in order to better understand their involvement and contribution to disease pathogenesis. In our previous study, enumeration of eosinophils after Epx mAb IHC indicated the presence of increased numbers of degranulated eosinophils in the upper and lower LP of the jejunum in dogs diagnosed with IBD compared with control dogs and dogs that had been treated for IBD.15 The current study confirms this observation in the duodenum of dogs with EE or mixed enteritis. In both cases, the number of degranulated eosinophils was significantly higher than in control dogs. The presence of an increased number of degranulated eosinophils in the upper and lower LP may be a previously unrecognized feature of IBD. Previous studies indicate that eosinophil granule proteins (eg, eosinophil cationic protein, major basic protein) released by activated eosinophils contribute to tissue damage and inflammation during GI disorders and may be indicative of active ongoing disease.30,33,34

Interestingly, in the current study, tissue from dogs with EE and mixed enteritis had similar numbers of intact and degranulated eosinophils after Epx mAb IHC, suggesting that eosinophils are an important cellular component of disease pathogenesis in both of these histologic forms of IBD. Eosinophil peroxide mAb-based IHC clearly differentiates between mild and moderate disease based on the number of intact eosinophils in the lower and upper LP. Furthermore, a consistently higher number of degranulated eosinophils was found in duodenal tissue from dogs with moderate disease compared to dogs with mild disease, although it did not reach statistical significance. Although one would expect degranulation to correlate with severity, it is still unclear how many eosinophils must degranulate to increase disease severity, and our study group may not have been large enough (ie, small sample size) to establish a statistically significant difference. Furthermore, discordance may exist between histological changes and severity of disease, and a disease activity index was not calculated for these dogs. Similarly, in our previous study a significant difference in the number of intact eosinophils was noted between dogs with IBD (untreated) and treated IBD dogs, albeit only in the upper LP.15 Based on the observation that H&E staining resulted in an underrepresentation of the number of eosinophils (intact relative to Epx mAb IHC not only in the duodenum but also in the stomach and colon in the current study, it is possible that evaluation of biopsy specimens by H&E stain only may result in underdiagnosis of disease as well as severity of disease in dogs with EGID.

A limitation of our study is that the control group consisted of dogs with various GI signs but with histologically normal intestinal biopsy specimens and were not healthy controls. Additionally, information regarding the diets that the dogs were fed was limited and therefore could not be controlled in the study. Evaluating the correlation of Epx mAb IHC to treatment outcome (ie, diet), can be the basis of a future investigation. Overall, we have demonstrated that detection of eosinophils by IHC with Epx mAb provides a more accurate and reliable method for detection of tissue-infiltrating eosinophils in duodenal biopsy specimens for the diagnosis of EGIDs such as IBD in dogs. This technique can be used as an alternative or additional diagnostic tool in assessment of dogs with IBD. Importantly, Epx mAb-based IHC allows for the assessment of eosinophil degranulation and thus enables a better understanding of the role of eosinophils and their granule proteins in the pathogenesis of IBD in dogs.
